Abstract

DNA double-strand breaks (DSBs) can be resolved by homologous recombination (HR), which can involve Holliday junction (HJ) intermediates that are ultimately resolved by nucleolytic enzymes. An N-terminal fragment of human GEN1 has recently been shown to act as a Holliday junction resolvase, but little is known about the role of GEN-1 in vivo. Holliday junction resolution signifies the completion of DNA repair, a step that may be coupled to signaling proteins that regulate cell cycle progression in response to DNA damage. Using forward genetic approaches, we identified a *Caenorhabditis elegans* dual function DNA double-strand break repair and DNA damage signaling protein orthologous to the human GEN1 Holliday junction resolving enzyme. GEN-1 has biochemical activities related to the human enzyme and facilitates repair of DNA double-strand breaks, but is not essential for DNA double-strand break repair during meiotic recombination. Mutational analysis reveals that the DNA damage-signaling function of GEN-1 is separable from its role in DNA repair. GEN-1 promotes germ cell cycle arrest and apoptosis via a pathway that acts in parallel to the canonical DNA damage response pathway mediated by RPA loading, CHK1 activation, and CEP-1/p53-mediated apoptosis induction. Furthermore, GEN-1 acts redundantly with the 9-1-1 complex to ensure genome stability. Our study suggests that GEN-1 might act as a dual function Holliday junction resolvase that may coordinate DNA damage signaling with a late step in DNA double-strand break repair.

Introduction

The correct maintenance and duplication of genetic information is constantly challenged by genotoxic stress. DNA double-strand breaks (DSBs) are amongst the most deleterious lesions. DSBs can be induced by ionizing irradiation (IR) or caused by the stalling of DNA replication forks. In response to DSBs, cells activate conserved DNA damage checkpoint pathways that lead to DNA repair, to a transient cell cycle arrest, or to apoptosis and senescence. The full activation of DNA damage response pathways and DSB repair by homologous recombination (HR) depends on a series of nucleolytic processing events. Following DSB formation, broken ends are resected in a 5’ to 3’ direction to generate 3’ single-strand overhangs [1]. These tails are coated by RPA1 molecules, which in turn are thought to lead to the recruitment of the ATR checkpoint kinase [2]. This kinase, and the related kinase ATM, appear to be directly targeted to DNA double-strand breaks to act at the apex of the DNA damage signaling cascade [3]. The DNA damage specific clamp loader comprised of Rad17 bound to the four smallest RFC subunits [4] recruits a PCNA-like complex referred to as “9-1-1” complex to the dsDNA-ssDNA transition of resected DNA ends [5–7]. The 9-1-1 complex is needed for full ATR activation [8,9]. DSB repair by HR proceeds by replacing RPA1 with the RAD51 recombinase [10,11]. The resulting nucleoprotein filament invades an intact donor DNA to form a D-loop structure. The invading strand is extended using the intact donor strand as a template. Annealing of the 3’ single-stranded tail of the second resected DNA end to the displaced donor DNA strand (second end capture), and DNA ligation lead to the formation of a double Holliday junction (dHJ) intermediate (for a review, see [12]). This dHJ must be resolved either through cleavage by Holliday junction (HJ)-resolving enzymes or through “dissolution” by the combined activity of the Blooms helicase and topoisomerase III [13,14].

Prototypic HJ resolving enzymes are nucleases that resolve HJs by introducing two symmetrical cleavages that result in either crossover or non-crossover products, depending on which strands

Author Summary

Coordination of DNA repair with cell cycle progression and apoptosis is a central task of the DNA damage response machinery. A key intermediate of recombinational repair and meiotic recombination, first proposed in 1964, involves four-stranded DNA structures. These intermediates have to be resolved upon completion of DNA repair to allow for proper chromosome segregation. Using forward genetics, we identified a Caenorhabditis elegans dual function DNA double-strand break repair and DNA damage signaling protein orthologous to the human GEN1 Holliday junction resolving enzyme. GEN-1 facilitates repair of DNA double-strand breaks, but is not essential for DNA double-strand break repair during meiotic recombination. The DNA damage signaling function of GEN-1 is separable from its role in DNA repair. Unexpectedly, GEN-1 defines a DNA damage-signaling pathway that acts in parallel to the canonical pathway mediated by CHK-1 phosphorylation and CEP-1/p53. Thus, an enzyme that can resolve Holliday junctions may directly couple a late step in DNA repair to a pathway that regulates cell cycle progression in response to DNA damage.

are cleaved. Cuts made by junction-resolving enzymes need to be perfectly symmetrical so that products can be re-ligated, thus requiring no further processing events for HJ resolution [15,16]. Until recently, the molecular nature of canonical HJ resolvases in animals and plants remained enigmatic despite the observation of HJ-resolution activity in cellular extracts over many years [17,18]. Resolving enzymes have been purified from bacteriophages, bacteria and archaea but the only eukaryotic resolving enzymes that had been discovered until recently were S. cerevisiae Cce1 and S. pombe Ydc2, both of which act in mitochondria [15,19,20]. One possible pathway of HJ resolution involves the conserved MUS81/EME1 complex, probably the principal meiotic resolution activity in fission yeast [21,22], although mouse as well as budding yeast strains lacking Mus81 only have very minor meiotic phenotypes [23,24]. By comparison with known resolving enzymes, the in vitro properties of this complex currently appear somewhat imprecise, and more akin to flap endonuclease action [25], yet recent evidence suggests that this complex can lead to productive HJ resolution [26,27]. In addition, it was recently shown that a complex between the SLX4 scaffold protein and the SLX1 nuclease can act as an HJ resolving enzyme [28–30]. Intriguingly, SLX4 also interacts with the XPF and MUS81 nucleases, providing a scaffold for repairing multiple DNA structures and the sequential action of SLX4/nuclease complexes on HJ might rather be described as HJ processing that nevertheless ultimately leads to HJ resolution [28–32]. While recent studies suggest that the SLX4 scaffold and associated nucleases may promote nuclease-dependant HJ resolution, an independent enzyme with HJ resolution activity, mammalian GEN1, was identified in vitro via biochemical fractionation [33]. GEN1 generates symmetrical nuclease-dependent HJ resolution, an independent enzyme with the SLX4 scaffold and associated nucleases may promote

We use the Caenorhabditis elegans germ line as a genetic system to study DNA repair and DNA damage response pathways. As part of the C. elegans life cycle invariant embryonic cell divisions occur very rapidly. Embryonic cells tolerate a relatively high level of DNA damage using error prone polymerases, possibly a result of natural selection that favours rapid embryonic divisions at the expense of genome integrity [36]. In contrast, the C. elegans germ line, which is the only proliferative tissue in adult worms, displays longer cell cycles and is much more sensitive to DNA damaging agents. The gonad contains various germ cell types arranged in a distal to proximal gradient of differentiation (Figure 1G). At the distal end of the gonad cell proliferation occurs in a mitotic stem cell compartment. This compartment is followed by the transition zone where early events of prophase I, such as double strand break generation and the initiation of meiotic chromosome pairing occur. Proximal to the transition zone most germ cells are arrested in the G2 cell cycle phase and reside in meiotic pachytene, where homologous chromosomes are tightly aligned to each other as part of the synaptonemal complex. Germ cells subsequently complete meiosis and concomitantly undergo oogenesis and arrest at the metaphase I stage of meiosis before they are fertilized at the proximal end of the gonad. It takes approximately 20 hours for pachytene stage cells to mature and get fertilized, while the progression of mitotic germ cells till fertilization takes approximately 48 hours [37,38]. DNA damage such as IR or replication stress, leads to prolonged G2 cell cycle arrest of mitotic germ cells. In addition, late stage meiotic pachytene cells undergo apoptosis in response to DNA damaging agents [39]. DNA damage responses are mediated by components of a conserved DNA damage response pathway (for a review see [40]). Upstream sensors and transducers such as the worm ATR ortholog or components of the 9-1-1 complex promote all DNA damage responses including DNA repair, cell cycle arrest and apoptosis. In contrast, downstream effectors like cep-1, which encode the sole primordial p53-like protein of C. elegans, are only needed for IR-induced apoptosis [41].

Using unbiased genetic screening and positional cloning approaches we have cloned the C. elegans homolog of the human GEN1 HJ resolving enzyme. C. elegans gen-1 is required for repair of DNA damage-induced DSBs. Surprisingly, gen-1 mutants are defective in IR-induced cell cycle arrest and apoptosis, indicating that GEN-1 promotes DNA damage signaling. The function of GEN-1 in apoptosis induction is independent of the ATL-1 (C. elegans ATR)-dependent induction of the CEP-1/p53 target EGL-1. Our results suggest that GEN-1 is a dual function protein required for the repair of DSBs as well as for DNA damage checkpoint signaling.

Results

A screen for C. elegans DNA damage response signaling mutants

To uncover new genes involved in DNA damage response signaling, we chose an unbiased genetic approach and screened for C. elegans mutants hypersensitive to IR and/or defective in DNA damage-induced cell cycle arrest and apoptosis. During C. elegans development, the majority of cell divisions occur during embryogenesis. In contrast, germ cell proliferation, which commences with two germ cells at the L1 larval stage, predominates in the following three larval stages and continues in adult worms, where all somatic cells are post-mitotic, but continued germ cell proliferation results in a steady state level of gen-1 homolog, complements the meiotic defect associated with mus81 [35].

We use the Caenorhabditis elegans germ line as a genetic system to study DNA repair and DNA damage response pathways. As part of the C. elegans life cycle invariant embryonic cell divisions occur very rapidly. Embryonic cells tolerate a relatively high level of DNA damage using error prone polymerases, possibly a result of natural selection that favours rapid embryonic divisions at the expense of genome integrity [36]. In contrast, the C. elegans germ line, which is the only proliferative tissue in adult worms, displays longer cell cycles and is much more sensitive to DNA damaging agents. The gonad contains various germ cell types arranged in a distal to proximal gradient of differentiation (Figure 1G). At the distal end of the gonad cell proliferation occurs in a mitotic stem cell compartment. This compartment is followed by the transition zone where early events of prophase I, such as double strand break generation and the initiation of meiotic chromosome pairing occur. Proximal to the transition zone most germ cells are arrested in the G2 cell cycle phase and reside in meiotic pachytene, where homologous chromosomes are tightly aligned to each other as part of the synaptonemal complex. Germ cells subsequently complete meiosis and concomitantly undergo oogenesis and arrest at the metaphase I stage of meiosis before they are fertilized at the proximal end of the gonad. It takes approximately 20 hours for pachytene stage cells to mature and get fertilized, while the progression of mitotic germ cells till fertilization takes approximately 48 hours [37,38]. DNA damage such as IR or replication stress, leads to prolonged G2 cell cycle arrest of mitotic germ cells. In addition, late stage meiotic pachytene cells undergo apoptosis in response to DNA damaging agents [39]. DNA damage responses are mediated by components of a conserved DNA damage response pathway (for a review see [40]). Upstream sensors and transducers such as the worm ATR ortholog or components of the 9-1-1 complex promote all DNA damage responses including DNA repair, cell cycle arrest and apoptosis. In contrast, downstream effectors like cep-1, which encode the sole primordial p53-like protein of C. elegans, are only needed for IR-induced apoptosis [41].

Using unbiased genetic screening and positional cloning approaches we have cloned the C. elegans homolog of the human GEN1 HJ resolving enzyme. C. elegans gen-1 is required for repair of DNA damage-induced DSBs. Surprisingly, gen-1 mutants are defective in IR-induced cell cycle arrest and apoptosis, indicating that GEN-1 promotes DNA damage signaling. The function of GEN-1 in apoptosis induction is independent of the ATL-1 (C. elegans ATR)-dependent induction of the CEP-1/p53 target EGL-1. Our results suggest that GEN-1 is a dual function protein required for the repair of DSBs as well as for DNA damage checkpoint signaling.
Figure 1. gen-1 mutants are defective in DNA damage–dependent cell cycle arrest and apoptosis and in positional cloning of GEN-1.

(A) Representative pictures of N2-wild type and gen-1 mitotic germ lines with and without IR treatment (60 Gy). Germ lines were dissected and stained with DAPI. Scale bar 10 μm. (B) Statistical analysis of cell cycle arrest. All mitotic germ cells within 50 μm from the distal tip cell were counted (n=7, error bars represent s.e.m.). (C) DNA damage-induced germ cell apoptosis is defective in gen-1 mutant worms (n=15, error bars represent s.e.m.). Germ cell apoptosis was assayed as described [41]. (D) gen-1 mutant germ cells fail to arrest in G2. Dissected germlines were stained with the human Cdk-1 phosphotyrosine 15 antibody [42] as a G2 marker (red). (E) Mapping of gen-1(yp30). Linkage to the centre of chromosome III is shown in the upper panel. The ratio of yp30 versus “Hawaiian” DNA measured at various single nucleotide polymorphisms. Single recombination events placing yp30 map position between SNPs located at map position -1,43 and -1,38 are indicated in the lower panel. (F) Chromatograms showing the C to T transition found in the gen-1 (yp30) mutant. (G) Diagram of an adult hermaphrodite germ line adapted from [74].
~500 germ cells. In order to select for mutants hypersensitive to IR, worms mutagenised with ethyl methane sulphonate (EMS) were irradiated at the L1 stage with 60 Gy of IR. This dose of radiation does not overtly affect germ cell proliferation in wild type worms while mutants hypersensitive to IR display reduced levels of fertility (data not shown). Out of 906 F2 lines screened, 5 mutations (yp30, yp42 and yp45) were recovered for the yp30 complementation group, each of which was derived from an independently mutagenised Po animal. In C. elegans, treatment of L4 larvae with IR leads to the activation of a DNA damage response checkpoint pathway that triggers apoptosis of meiotic pachytene stage germ cells, and a transient halt of mitotic germ cell proliferation leading to enlarged cells [39]. This latter phenotype results from continued cellular growth in the absence of cell division. The yp30 complementation group does not exclude mitotic germ cells upon IR of L4 larvae, similar to the mrt-2 (y2663) checkpoint mutant (Figure 1A and 1B, Figure S1B) [39], and is partially defective in DNA damage-induced apoptosis (Figure 1C). We did not find any further mutants, which were defective in both IR-induced cell cycle arrest and apoptosis like the yp30 complementation group (data not shown). To show that yp30 germ cells do indeed fail to arrest cell cycle progression after irradiation, we stained N2 wild type and yp30 mutants with antibodies against phosphorylated tyrosine-15 CDK-1, which serves as a G2 marker [42, 43]. We found that wild type germ cells arrest in G2, whereas yp30 germ cells fail to do so (Figure 1D), a finding we confirmed using a YFP::Cyclin B1 fusion construct as a G2 marker (Figure S1A). To clone the gene corresponding to yp30, we followed the cell cycle arrest-defective phenotype in backcrossing, SNP-mapping and complementation experiments and positioned yp30 close to the centre of chromosome III, between dpy-17 and unc-32, to an interval of approximately 135,000 base pairs (Figure 1E, data not shown). Sequencing this interval in yp30 worms revealed two mutations, one in an intergenic region, and one that leads to a premature stop codon in a gene encoding for a conserved nuclease we refer to as gen-1 (see below, Figure 1F, Figure 2A), yp42 and yp45 also contained the same C to T point mutation as gen-1(yp30), but lacked the intergenic mutation found in yp30. Sequencing of the gen-1 cDNA confirmed the predicted gen-1 cDNA sequence and the predicted intron-exon structure of gen-1, available from Wormbase (http://www.wormbase.org/; data not shown). A gen-1 deletion allele, gen-1(tm2940) (Figure 2A) obtained from the Japanese C. elegans knockout consortium, as well as gen-1 (RNAi), similarly lead to a cell cycle arrest defect upon irradiation (Figure S1B). In addition, the same phenotype was observed in gen-1 (tm2940)/gen-1(yp30) trans-heterozygotes (Figure S1B). Time course and dose response experiments revealed that gen-1(tm2940), gen-1(yp30) and mrt-2 (y2663) worms are equally defective in IR induced cell cycle arrest (Figure S2). Furthermore, gen-1(tm2940) is largely defective in DNA damage-induced apoptosis, similar to cep-1(qc2501), a deletion mutant of the C. elegans p53-like gene cep-1 [41, 44] (Figure 1C). In summary, our data reveal that gen-1 is required for IR-induced apoptosis and cell cycle arrest in C. elegans germ cells.

**GEN-1 assignment and phylogenetic relationships**

Sequence alignments suggest that GEN-1 is a member of the XPG super-family of nucleases, members of which contain two conserved domains referred to as N and I domains as part of the catalytic centre [45] (Figure 2A, Figure S3). GEN-1 contains putative catalytic residues known to be required for nuclease activity, these are aspartate 77 located in the N domain and glutamate 791 within the I domain of human XPG (Figure S3) [46]. We analyzed all XPG-like genes from fungi, some invertebrates (including other nematodes) and vertebrates, finding that all sequences clustered within four classes of nucleases GEN1, XPG, FEN1 and EXO1, with high probability scores in all species except for fission yeast that does not encode for GEN1 (Figure 2B and 2C). XPG is involved in nucleotide excision repair [47], FEN1 is a flap nuclease involved in latching strand DNA replication [48, 49], and EXO1 is implicated in genomic stability, telomere integrity [50] as well as DSB end resection [51, 52]. GEN1 was first biochemically characterized based on its flap endonuclease activity in *Drosophila*, and named DmGEN1 (XPG like Endonuclease-1) [53]. A human GEN1 N-terminal fragment was recently purified from HeLa cell extracts, and shown to have robust Holliday junction-resolving activity. Moreover an activity was also found in crude preparations of the budding yeast ortholog Yen1p [33]. The gen-(yp30) mutation leads to the expression of a C-terminally truncated protein that does not affect the putative catalytic centre (Figure 2A and 2D). In contrast, the tm2940 deletion is predicted to eliminate the majority of the I domain and is likely to be a null allele, as anti-GEN-1 antibodies detected GEN-1 protein for wild-type and gen-1(yp30) strains but not for gen-1(tm2940) (Figure 2A and 2D, Figure S7B and S7C).

To determine if C. elegans GEN1 exhibits Holliday junction-resolving activity in vitro, as predicted from homology to the human GEN1, recombinant wild type GEN-1, GEN-1 (yp30) and an E155A mutant were expressed and purified, the latter bearing a mutation in one of the putative nuclease active site residues (Figure S4A). A Holliday junction-resolving enzyme should symmetrically cleave Holliday junctions and be specific for four-way DNA junctions. We tested for GEN-1 nuclease activity on two four-way DNA junctions, Jbm5 contains a 12 base pair homologous core through which the branch point can migrate [34] and X26 contains a 26 base pair core and bears sequences unrelated to Jbm5 [33]. Using both four-way junction substrates we observed specific cleavage using GEN-1 and GEN-1 (yp30) recombinant enzymes (Figure 2E). Using both substrates the same cleavage pattern was observed on opposite strands as expected from symmetry (Jbm5, Figure 2F, data not shown). To confirm structural specificity towards four-way DNA junctions, we tested whether C. elegans GEN-1 showed specific nuclease activity towards a variety of other substrates, including single-stranded, blunt double-stranded DNA, a dsDNA substrate with a 3’ single-stranded overhang, and a 5’ flap structure. We observed no specific cleavage of any of these substrates with C. elegans GEN-1 (Figure 2G, Figure S4C). Comparing the cleavage to that generated by the human GEN1 (comprising amino acids 1-527), we find that the major Jbm5 cleavage product resulting from incubation with human GEN1 also occurs upon incubation with the C. elegans protein (Figure S4B). Human GEN1 also showed an activity towards 5’ flap structures as reported previously [33] (Figure S4C). The enzymatic activity of the recombinant C. elegans enzyme is relatively low; we thus cannot exclude the possibility that C. elegans GEN1 also shows a 5’ flap activity, albeit we did not observe such an activity in overexposed gels and multiple repeat experiments. We speculate that the low activity of recombinant C. elegans GEN1 might be due to improper folding. Alternatively, the worm nuclease might require post-translational modifications, interacting proteins or activation by proteolytic cleavage to become fully activated as a HJ resolving enzyme, thereby preventing us from undertaking a more thorough analysis of its biochemical properties at the present time. Nevertheless, the cleavage introduced into the four-way junction by C. elegans GEN-1 as well as the orthologous relationship to human GEN1 and budding yeast Yen1p, is consistent with GEN-1 being a junction-resolving enzyme in *C. elegans*.

[42, 43]...
GEN-1 is required for DNA double-strand break repair

A Holliday junction-resolving activity is likely to be required for mitotic recombination, and a defect in this activity is predicted to result in embryonic lethality due to random autosome segregation in meiosis [55]. We can exclude such a defect as gen-1(tm2940) worms propagate as wild type, and fail to exhibit embryonic lethality in the absence of genotoxic stress (Figure 3A (0 Gy)). Furthermore, we did not observe an enhanced incidence of XO males, a phenotype that would indicate defects in meiotic chromosome pairing or recombination of the X chromosome (Table 1) [56].

Most C. elegans mutations of DNA damage checkpoint genes, such as hph-17, encoding for the Replication Factor C homolog of S. pombe Rad17, are also considered to be required for DNA DSB repair, as the corresponding mutants are hypersensitive to IR [39]. Two assays allow for testing the IR sensitivity of cells residing in different germ line compartments. In the “L1” IR survival assay that corresponds to the screening conditions we initially used to isolate yp30 as an IR sensitive mutant, the sensitivity of mitotic germ cells is evaluated by irradiating L1 larvae and by assaying for sterility of the resulting adults. The extent of sterility is scored by counting the number of worms in the following generation. Upon irradiation, which causes lesions predominately repaired by excision repair (Figure 3D), neither DNA cross-linking by nitrogen mustard, which is largely repaired by the DNA interstrand cross link pathway, nor hydroxyurea which slows DNA polymerase processivity by nucleotide depletion, led to hypersensitivity in gen-1 mutants (Figure 3E and 3F). To corroborate our results, we also employed the L4 irradiation assay [38]. In the “L4” IR assay, the sensitivity of meiotic pachytene cells is determined by measuring survival of embryos that are produced ~20 hours after irradiation; these embryos are derived from pachytene cells that are arrested in the G2 cell cycle stage for more than 10 hours prior to completing meiosis and oogenesis. We found that both gen-1(tm2940) and gen-1(RNAi) are as IR-sensitive as the hph-17(tm1579) deletion, whereas gen-1(yp30) pachytene germ cells were not sensitive to IR (Figure 3B). A similar response profile was found in response to MMS treatments (Figure S3A), while no enhanced sensitivity was found in response to UV, nitrogen mustard, or hydroxyurea (Figure S5B and S5D). Thus, the gen-1(yp30) allele, which results in a C-terminally truncated protein that retains nuclease activity in vitro, elicits IR- and MMS-induced hypersensitivity for mitotic germ cells of L1 larvae, whereas a null gen-1 mutation displays additional hypersensitivity to these agents in L4 germ cells arrested in pachytene. Our results suggest that the signaling function of GEN-1 is likely conferred by the C-terminus of GEN-1, given that the gen-1(yp30) allele is a null allele, encoding for the Replication Factor C homolog of S. pombe Rad17, and is therefore considered to be required for DNA DSB repair, as the corresponding mutants are hypersensitive to IR [39].

To test if the IR sensitivity phenotypes of gen-1 mutants correlate with persistence of DSBS, we assayed for RAD-51 foci. At doses where multiple DSBS per cell are generated, the number of persistent RAD-51 foci in mitotic germ cells of mrt-2(e2663) and both gen-1 mutants is higher as compared to wild type, indicating a DSB repair defect (Figure 4). To directly confirm whether IR leads to increased DNA double-strand breakage in gen-1 mutant worms we directly assayed for chromosome fragmentation after irradiation with 90 Gy. As shown previously [59], 48 hours after irradiation of mitotic germ cells (at the L4 stage) the diakinesis chromosomes of resulting mrt-2(e2663) oocytes were fragmented. In contrast, IR-induced damage was repaired in wild type, where oocyte chromosomes appear as 6 morphologically intact condensed DAPI stained structures (Figure 5A and 5B). Chromosome fragmentation for both gen-1 mutants was as strong as that observed for the mrt-2 positive control, indicating a defect in DSB repair. This chromosome fragmentation phenotype was not observed as a consequence of irradiating pachytene stage cells and observing corresponding oocytes ~8 hours and ~20 hours after IR (Figure 5C). Given that gen-1(tm2940) and gen-1(yp30) are equally defective in repairing diakinesis chromosomes 48 hours after irradiation we consider it likely that the checkpoint functions of gen-1 and mrt-2 in mitotic germ cells contribute to DSB repair. Given that DSBS inflicted in pachytene cells are repaired in gen-1 and mrt-2 mutants while this is not the case for DSBS in mitotic germ cells there might be a stronger requirement of GEN-1 and MRT-2 for DSB repair in mitotic germ cells.
GEN-1 may act in parallel to ATM and the 9-1-1 complex to facilitate DSB repair.

We next wished to determine if gen-1 acts in a known pathway promoting the repair of DSBs. We first examined if gen-1 affects non-homologous DNA end joining. In *C. elegans* DNA end joining is predominantly used in somatic cells. Worms defective in DNA end joining genes such as *lig-4*, *cka-70* and *cka-80* show a reduced pace of development upon IR of embryos [59]. We found that non-homologous DNA end joining.
neither of the gen-1 mutants exhibited any such somatic developmental delay (Figure S7A). The strong IR-sensitivity and the defect in checkpoint-dependent cell cycle arrest and apoptosis of gen-1(tm2940) is reminiscent of the phenotype of mutations in upstream DNA damage signaling factors such as the C. elegans 9-1-1/Replication Factor C-like complex members hus-1 and mrt-2 (S. pombe rad1). Given that mutations of genes encoding for the 9-1-1 complex lead to telomere replication defects [60], we asked if sterility in later generation worms caused by progressive telomere attrition occurs in gen-1(tm2940). We failed to observe such an effect, further indicating that gen-1 is not part of the mrt-2 epistasis group (Figure S8A).

To investigate further how GEN-1 affects DNA damage responses, we depleted gen-1 in hus-1 or mrt-2 mutant backgrounds. RNAi depletion of gen-1 in hus-1 or mrt-2 mutant strains leads to synthetic lethality (Figure 6B). We confirmed this synthetic lethality by gen-1 hpr-17 double mutant analysis (Figure S8B). hpr-17 encodes for the 9-1-1 clamp loader and is part of the mrt-2 epistasis group. As expected, gen-1 RNAi in a mrt-2(e2663) background led to an increased number of RAD-51 foci as compared to gen-1 RNAi in wild type worms and to the mrt-2(e2663) mutant in mitotic germ cells (Figure S9). In contrast, gen-1(yp30), which is checkpoint-defective but encodes a protein that can promote HJ resolution in vitro, did not cause synthetic lethality when combined with an hpr-17 mutation, nor did it exacerbate the radiation hypersensitivity phenotype of hpr-17 (Figure S8C). These results therefore suggest that the DNA repair function of GEN-1 may act redundantly with the 9-1-1 complex to repair DSBs occurring during normal DNA replication.

We next wished to determine genetic interactions between GEN-1, ATR and ATM PI3-like kinases, which are predicted to act upstream of the 9-1-1 complex in DNA damage signaling. Given that an atl-1(tm853) deletion leads to excessive genome instability in germ cells and concomitant sterility [61], we could not assess the possibility of enhanced IR sensitivity in gen-1 atl-1

double mutants. In contrast, *C. elegans* *atm-1* plays a minor role in DNA damage signaling and *atm-1*(gk186) results in partial defect in IR-induced cell cycle arrest and apoptosis [62]. Consistent with this notion, we found that the *atm-1*(gk186) deletion is not hypersensitive to IR when subjected to the L4 IR survival assay, and that the IR sensitivity is not enhanced by the *gen-1*(yp30) mutant (Figure S10). In contrast, the *atm-1*(gk186) mutant is sensitive to IR in the L1 assay, and IR sensitivity is enhanced in combination with both *gen-1*(tm2940) and *gen-1*(yp30) (Figure 7).

In summary, our results suggest that *gen-1* might act in parallel to *atm-1* for repairing mitotic germ cells affected by DNA double-stranded breaks.

**GEN-1 may act in parallel to the chk-1 cep-1/p53 checkpoint pathway**

Given that *gen-1* encodes for a nuclease, we wanted to eliminate the possibility that GEN-1 might also be required for the processing of DSBs to generate single-stranded DNA overhangs, which would be coated by RPA1 and lead to the ATRIP-dependent activation of ATR in mammalian cells [2]. We thus tested whether IR-dependent RPA1 loading is compromised in *gen-1*(tm2940) worms. We found that the sequential accumulation of RPA-1 (green) and RAD-51 (red) foci does not significantly differ between wild type and *gen-1*(tm2940) worms, indicating that the initial steps of DSB processing occur normally in *gen-1* mutants (Figure S6A). These results are corroborated by our finding that GEN-1 does not cleave double-stranded substrates or substrates with 3’ single stranded overhangs *in vitro* (Figure 2G).

To monitor the activation of the *C. elegans* ATL-1/ATR-mediated DNA damage checkpoint pathway in *gen-1*(tm2940) mutants, we analyzed the IR-induced transcriptional induction of the pro-apoptotic BH3-only domain encoding genes *ced-13* and *egl-1*. The induction depends on the *C. elegans* CEP-1 p53-like transcription factor [63], and on upstream DNA damage response

---

genes including atl-1 (C. elegans ATR), clk-2, has-1 and mrt-2 [64].
egl-1 and cep-13 were induced to near-normal levels for tm2940 and
yp30 alleles of gen-1, while no induction occurred in a cep-1
(lg12501) background (Figure 6A). Thus, the apoptotic signaling
function of GEN-1 acts in parallel to the canonical C. elegans DNA
damage response pathway necessary for egl-1 induction. To further
support this notion, we cytologically probed for the activation of
CHK-1, which is required for IR-induced cell cycle arrest and
apoptosis in C. elegans [65]. To this end we employed an antibody
against a conserved CHK-1 phosphopeptide that includes serine
345 [36,66]. Phosphorylation of this residue in response to DNA
damage depends on ATR and ATM kinases and leads to Chk1
activation in mammals [67–69] and occurs in response to ATR-1/
ATR activation in C. elegans [36,66]. CHK-1 phosphorylation is
increased in response to IR in cell cycle arrested cells (Figure 6C,
top panel), both in wild type as well as in gen-1 mutants, further
substantiating the notion that the checkpoint signaling function of
GEN-1 might act in parallel to the canonical pathway. Interestingly,
CHK-1 phosphorylation also occurs in the mrt-2 (e2663) mutant (Figure 6C). This data indicates that ATM/ATR is
not fully dependent on mrt-2, consistent with the reduction as
opposed to the complete alleviation of GEN-1 dependent
transcription in this mutant [64]. Thus our results suggest that
gen-1 and mrt-2 act in parallel pathways needed for checkpoint
signaling similar to their roles in DSB repair.

Discussion

We have discovered that the deficiency of GEN-1 results in
DNA damage signaling defects (Figure 8). Neither cell cycle arrest
of mitotic germ cells, nor apoptosis induction of meiotic pachytenic
cells occurs in response to DNA damage in gen-1 mutants. These
defects are as severe as those observed in known C. elegans
checkpoint mutants such atl-1, the worm ATR homolog [61], clk-2
[70] and mutants affecting components of the C. elegans 9-1-1
complex [60,71,72]. Intriguingly, we find that the apoptosis defect
conferred by a mutation in gen-1 does not result from the ATR-,
CLK-2 and 9-1-1 complex-dependent activation of the primordial
worm p53-like protein CEP-1 (Figure 8) [41,44]. The two
known CEP-1 target genes egl-1 and cep-13, whose transcriptional
activation confers the inhibition of the anti-apoptotic Bcl2 like
protein CED-9, are normally induced [63]. Thus, the signaling
function of GEN-1, which promotes apoptosis in meiotic germ
cells, appears to be in a pathway acting in parallel or downstream
of the canonical DNA damage response pathway that activates
CEP-1/p53. Analogous results have been observed for C. elegans
sir-2.1 histone deacetylase, as well as for hyl-1 and lagr-1 ceramide
synthase mutants, where CEP-1 targets are upregulated in
response to DNA damage even though germ cell apoptosis fails
to occur [73,74]. Thus, gen-1, sir-2.1, hyl-1 and lagr-1 may define
components of a DNA damage response pathway that functions in
parallel to the pathway, which needs CHK-1 and the 9-1-1
complex. How these pathways are integrated remains to be
echilicated. We speculate that GEN-1 may facilitate DSB repair by
coordinating cell cycle progression with HJ resolution.

Our evidence that C. elegans GEN-1 acts as a HJ-resolving
enzyme is supported by the biochemical characterization of its
human and yeast orthologs [33]. Given the orthologous relation-
ship with C. elegans GEN-1 and our biochemical evidence, it is
likely that C. elegans GEN-1 can act as a HJ-resolving enzyme in
vivo. The active form of GEN-1 purified form HeLa cell extracts is
a C-terminal truncation [33]. We analyzed multiple preparations
of full length and truncated versions of C. elegans GEN-1 but could
only obtain weak nuclease activity on mobile HJ substrates.
Nevertheless, this activity is lost if one of the putative active site
residues was mutated, and it was specific for Holliday junction
transitions.
substrates. Thus, the nuclease function of *C. elegans* GEN-1 during DSB repair may involve HJ resolution. Future studies may refine our understanding of the substrate specificity of GEN-1.

Our results point towards the possibility that the completion of HJ resolution in response to DNA damage-induced DSBs might be monitored by GEN-1, which might act both as a Holliday junction-resolving enzyme as well as a DNA damage signaling molecule (Figure 8). A dual function enzyme that catalyses a late step of recombination and plays a role in checkpoint signaling could provide a mechanism to suppress cell cycle progression to allow for the repair of the majority of DNA double-strand breaks before cell cycle progression resumes. The signaling function of GEN-1 is likely conferred by the C-terminus of GEN-1. The C-terminus of GEN-1 may therefore interact with known or novel DNA damage signaling molecules that function to promote DSB repair in mitotic germ cells.

At the moment we can only speculate about the nature of the RAD-51 foci that persist in gen-1 mutants. Some of these RAD-51 foci might correspond to recombination intermediates resulting from failure of specific types of checkpoint-mediated DNA repair. Alternatively, these foci might be the consequence of initial unrepaired DNA damage that result in double-strand breakage once unrepared DNA is replicated when cells resume cell division.

Given the specificity with which GEN-1 processes HJ structures *in vitro*, it is surprising that GEN-1 does not have any obvious function in meiotic recombination. One candidate for a *C. elegans* meiotic HJ-resolving enzyme might be the Him-18/SIX4/Mus312 SLX1 nuclease complex. The rate of meiotic recombination is significantly reduced in *Drosophila mus312* mutants [75], and the human SLX1/SIX4 complex has recently been shown to have HJ resolution activity *in vitro* [28–31]. Further, lack of a role for GEN-1 in meiotic crossover resolution is consistent with recent evidence that *Drosophila* and *C. elegans* him-18/six-4 may promote meiotic Holliday junction resolution [31,32]. Additional proteins implicated in resolving meiotic HJ initially in fission yeast and fruit flies are Mus81 and Xpf1, respectively [21,75]. Further, the combined activities of Bloom’s helicase and topoisomerase III have been shown to dissolve HJ independently of canonical junction-resolving activities *in vitro* [13,14]. However, the meiotic defects of the *C. elegans* mus-81, xpf-1 or him-6 Bloom’s orthologs are not overtly enhanced by the gen-1 (tm2940) mutation (Simon Boulton, personal communication). Collectively, the absence of a meiotic defect of gen-1 together with the lack of strong synthetic effects with candidate meiotic HJ resolving enzymes, strongly suggests that *C. elegans* GEN-1 does not play a central role in this process.

Although different species vary in their precise DNA double-strand break response strategies, and various cell types are likely to utilize different DSB repair pathways preferentially, basic regulatory complexes and processes tend to be conserved. *C. elegans* GEN-1 plays an essential role in responding to DSBs, but it is inert in budding yeast [34] and has apparently been lost during evolution of fission yeasts. In addition to DNA end-joining, which does not require HJ resolution, DSBs can be repaired without a HJ resolution step by DNA synthesis-dependent strand annealing [57,76,77]. We speculate that this may be related to an inherent redundancy in DNA double-strand break repair pathways in diverse organisms, and perhaps within various tissues of the same organism. Indeed, our staining for RAD-51 foci indicates that most DSBs are repaired in gen-1 mutants, likely by a combination of the above mentioned recombinational repair pathways and non-homologous end joining, but that a fraction of these breaks persists 48 hours after IR (Figure 4). Such a scenario is in line with recent data suggesting that a subset of persistent DBSs is repaired by distinct DSB repair pathways [59,78]. In mammals these persistent foci are associated with heterochromatin and their repair specifically requires ATM [79], which may be consistent with the enhanced DNA damage response defects observed for atm-1;gen-1 double mutants. Thus, GEN-1 might be involved in DSB repair processes that are redundant and therefore hidden within DSB response networks in some organisms.

It has recently been reported that GEN1 is absent in ovarian and colon cancer cell lines, suggesting that GEN1 is required for maintaining genome stability in human cells [80]. Thus, GEN1 might join the number of genes involved in recombinational repair such as BRCA1, BRCA2, and FANCJ/BACH, mutation of which is associated with cancer. Deletion of these genes does not result in
cellular lethality, but affected cancer cells are uniquely sensitive towards DNA damaging agents allowing their selective eradication. Redundant mechanisms involved in resolving HJ structures might be particularly amenable to such synthetic lethal approaches. Our finding that gen-1 is synthetically lethal with mutations in known DNA damage sensors and repair proteins encoded by the 9-1-1 complex suggests one such mechanism. Overall, our results show that GEN-1, a protein previously implicated in HJ resolution, possesses dual function that potentially couples DNA repair and DNA damage signaling.

Materials and Methods

**C. elegans** strains and maintenance

Worms were maintained at 20°C on NGM agar plates seeded with *E. coli* strain OP50 as previously described [81], unless otherwise indicated. Alleles are all described in the CGC *C. elegans* stock center. We generated the following strains as part of this study TG1043 gen-1(yp30)III; TG1540 gen-1(tm2940)III; TG765 cep-1(gk12501)I; TG1236 gen-1(yp30) unc-22[rx189]III; TG1237 gen-1(yp30) dpy-17(e164)III; TG1233 hpr-17(m1579)I; TG771 hus-1(op244)I; TG545 hus-1(op241)I; TG1503 hpr-17(m1579)II; gen-1(yp30)III; TG1502 gen-1(yp30)III; spj76(CYB-1::YPF); TG1064 gen-1(yp42)III; TG1060 gen-1(yp45)III; TG1565 xpg-1(tm1670); RB964 cka-80(ak861)III; TG190 ckd-2(m159)III; VC381 atm-1(gk186)I.

DNA damage-induced apoptosis and L4 radiation hypersensitivity (rad) assays were performed as described [39]. For γ-irradiation a Cs137 source (2.9 Gy/min, IBL 437C, CIS Bio International) was used.

Protein expression and GEN-1 antibody production

6x-histidine tagged full length GEN-1 (pGA343) was expressed in BL21(DE3) CodonPlus cells, recovered from inclusion bodies using BugBuster (Novagen), solubilised in Urea buffer and purified with Ni-NTA following manufacturer's instructions (Qiagen). One guinea pig was immunized (BioGenes GmbH) and antibodies were affinity-purified from the final bleeding using Malose Binding Protein (MBP) tagged protein. N- and C-terminus GEN-1 (fragments 1-136 and 336-434 respectively) tagged with MBP (pGA346 and pGA348) were purified using an amylose resin column (New England BioLabs). For affinity purification, proteins were covalently linked to AffiGel 15 (Bio-Rad).

Immunostainings

Immunostaining experiments were performed as described [74]. Primary antibodies used were rabbit anti-RAD-51 (1/200 dilution) as described [82], rat anti-RPA-1 (1/100 dilution), rabbit anti-Cdk1 (pTyr15) Calbiochem, 219440 (1/50 dilution) and rabbit anti-P-CHK1 (p-CHK1 Ser 345: sc-17922, Santa Cruz, 1/50 dilution). N- and C-terminus GEN-1 (fragments 1-136 and 336-434 respectively) tagged with MBP (pGA346 and pGA348) were purified using an amylose resin column (New England BioLabs). For affinity purification, proteins were covalently linked to AffiGel-15 (Bio-Rad) and used to affinity-purify antibodies from the final bleed.

**L1 genotoxic assays**

L1 larvae stage worms were sorted from a growing population using an 11 μm filter (Millipore NY11) and treated with the indicated genotoxic agents. To test MMS and Nitrogen mustard sensitivity, worms were incubated with the indicated concentration of mutagen for 12 hours in M9 buffer. UV irradiation was performed by the XL-1000 Spectrolinker UV-C light source. 5 L1 stage worms in the F0 generation were plated onto a single plate. The number of living worms (post the L1 stage) present in the F1 generation within 48 hours of (untreated) F0 worms reaching the L4 stage was counted using a dissection microscope. For hydroxyurea (HU), L1 worms were plated on 1x NGM plates supplemented with the indicated compounds and the living adult worms corresponding to the F1 generation were established similarly. Experiments were done at least in triplicate.

**RNAi feeding**

RNAi feeding was done as described with exception of using 1 mM IPTG [58].

**Cleavage assays**

Recombinant proteins (50 nM) were added to 2 nM (Figure S4) or 5 nM (Figure 2E-2G) of the indicated substrates all of which were 5' [33P]-labelled on one strand in 10 mM Tris-HCl pH 7.0, 10 mM NaCl, 10 mM MgCl₂, 0.1 mg/ml BSA, 0.1 mg/ml calf thymus DNA, 1 mM DTT and 1 M NDSB 201. Samples were incubated at 37°C for 30 min or overnight, and the reaction terminated by addition of EDTA. Cleavage products were analysed by electrophoresis in 12% polyacrylamide gels containing 8 M urea. Gels were dried and imaged using a Fuji BAS 1500 phosphorimager.

**Substrates**

For the nuclease assays, substrates were generated as described [33], the following oligonucleotides were used, sequences are shown 5' to 3':

- Single-stranded:
  - 5'-CGCTTCGAGCGCGGTATTAGCGCTGTTAGCGCTTAGG-3'
  - 5'-TAAGCTATTTATAAGGTTTGATGATGATGATG-3'

- Double-stranded (annealing 1971 and 1972):
  - 5'-CGCTTCGAGCGCGGTATTAGCGCTGTTAGCGCTTAGG-3'
  - 5'-TAAGCTATTTATAAGGTTTGATGATGATGATG-3'

**Supporting Information**

**Figure S1** Cell cycle arrest defects of the *yp30* complementation group. (A) *yp30* mutant worms fail to arrest at the G2 stage following DNA damage. Wild type and *yp30* worms expressing cyclin B1 fused to YFP (gift from Michael O. Hengartner), unirradiated or irradiated (60 Gy) and assayed after 8h. (B) Representative pictures of N2 wild-type and gen-1 mitotic germ lines with and without IR treatment. The black arrow depicts a small nucleus of an untreated wild type germ line. The white arrow indicates an enlarged nucleus in an IR treated wild type
germ line. Numbers in each panel indicate the respective numbers of nuclei. yp42, yp43, and yp30/tm2940 trans-heterozygotes are all defective in IR induced cell cycle arrest. The number of mitotic cells is indicated in each panel.
